Abstract—In this work, we propose a game theoretic framework to analyze the behavior of cognitive radios for distributed adaptive channel allocation. We define two different objective functions for the spectrum sharing games, which capture the utility of selfish users and cooperative users, respectively. Based on the utility definition for cooperative users, we show that the channel allocation problem can be formulated as a potential game, and thus converges to a deterministic channel allocation Nash equilibrium point. Alternatively, a no-regret learning implementation is proposed for both scenarios and it is shown to have similar performance with the potential game when cooperation is enforced, but with a higher variability across users. The no-regret learning formulation is particularly useful to accommodate selfish users. Non-cooperative learning games have the advantage of a very low overhead for information exchange in the network.

We show that cooperation based spectrum sharing etiquette improves the overall network performance at the expense of an increased overhead required for information exchange.

I. INTRODUCTION

With the new paradigm shift in the FCC's spectrum management policy [3] that creates opportunities for new, more aggressive, spectrum reuse, cognitive radio technology lays the foundation for the deployment of smart flexible networks that cooperatively adapt to increase the overall network performance. The cognitive radio terminology was coined by Mitola [15], and refers to a smart radio which has the ability to sense the external environment, learn from the history, and make intelligent decisions to adjust its transmission parameters according to the current state of the environment.

The potential contributions of cognitive radios to spectrum sharing and an initial framework for formal radio etiquette have been discussed in [16]. According to the proposed etiquette, the users should listen to the environment, determine the radio temperature of the channels and estimate their interference contributions on their neighbors. Based on these measurements, the users should react by changing their transmission parameters if some other users may need to use the channel.

While it is clear that this etiquette promotes cooperation between cognitive radios, the behavior of networks of cognitive radios running distributed resource allocation algorithms is less well understood.

As the cognitive radios are essentially autonomous agents that are learning their environment and are optimizing their performance by modifying their transmission parameters, their

interactions can be modelled using a game theoretic framework. In this framework, the cognitive radios are the players and their actions are the selection of new transmission parameters and new transmission frequencies, etc., which influence their own performance, as well as the performance of the neighboring players.

Game theory has been extensively applied in microeconomics, and only lately has received attention as a useful tool to design and analyze distributed resource allocation algorithms (e.g. [5][6][14]). Very recently, the spectrum sharing problem was analyzed in [7] based on a game model between providers using bargaining strategies. In [7], the bound of the price of anarchy was analyzed under the assumption that users are uniformly distributed, or every AP uses the same transmission power.

Some game theoretic models for cognitive radio networks were presented in [18], which has identified potential game formulations for power control, call admission control and interference avoidance in cognitive radio networks. The convergence conditions for various game models in cognitive radio networks were investigated in [19].

In this work, we propose a game theoretic formulation of the adaptive channel allocation problem for cognitive radios. Our current work assumes that the radios can measure the local interference temperature on different frequencies and can adjust by optimizing the information transmission rate for a given channel quality (using adaptive channel coding) and by possibly switching to a different frequency channel. The cognitive radios' decisions are based on their perceived utility associated with each possible action. We propose two different utility definitions, which reflect the amount of cooperation enforced by the spectrum sharing etiquette. We then design adaptation protocols based on both a potential game formulation, as well as no-regret learning algorithms. We study the convergence properties of the proposed adaptation algorithms, as well as the tradeoffs involved.

II. SYSTEM MODEL

The cognitive radio network we consider consists of a set of N transmitting-receiving pairs of nodes, uniformly distributed in a square region of dimension $D^* \times D^*$. We assume that the nodes are either fixed, or are moving slowly (slower than the convergence time for the proposed algorithms). Fig. 1 shows an example of a network realization, where we used dashed

lines to connect the transmitting node to its intended receiving node. The nodes measure the spectrum availability and decide

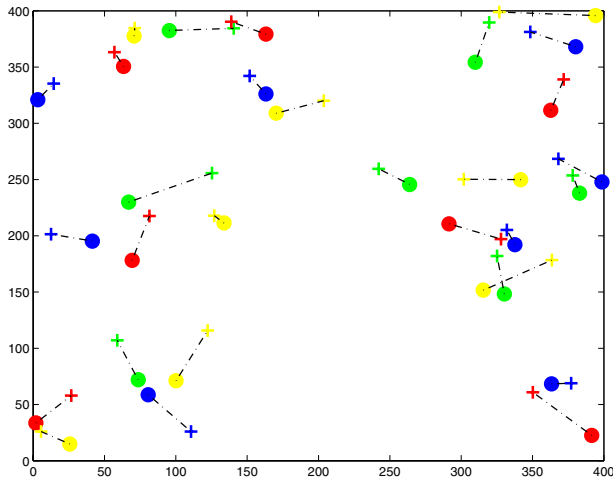

Fig. 1. A snapshot of the nodes' positions and network topology

on the transmission channel. We assume that there are K frequency channels available for transmission, with $K < N$. By distributively selecting a transmitting frequency, the radios effectively construct a channel reuse distribution map with reduced co-channel interference.

The transmission link quality can be characterized by a required Bit Error Rate (BER) target, which is specific to the given application. An equivalent SIR target requirement can be determined by the modulation type and the amount of channel coding.

The Signal-to-Interference Ratio (SIR) measured at the receiver j associated with transmitter i can be expressed as:

$$SIR_{ij} = \frac{p_i G_{ij}}{\sum_{k=1, k \neq i}^N p_k G_{kj} I(k, j)}, \quad (1)$$

where p_i is the transmission power at transmitter i , G_{ij} is the link gain between transmitter i and receiver j . $I(i, j)$ is the interference function characterizing the interference created by node i to node j and is defined as

$$I(i, j) = \begin{cases} 1 & \text{if transmitters } i \text{ and } j \text{ are transmitting} \\ & \text{over the same channel} \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

Analyzing (1) we see that in order to maintain a certain BER constraint the nodes can adjust at both the physical and the network layer level. At the network level, the nodes can minimize the interference by appropriately selecting the transmission channel frequency. At the physical layer, power control can reduce interference and, for a feasible system, results in all users meeting their SIR constraints. Alternatively, the target SIR requirements can be changed (reduced or increased) by using different modulation levels and various channel coding rates. As an example of adaptation at the physical layer, we have assumed that for a fixed transmission power level, software defined radios enable the nodes to adjust

TABLE I
CODE RATES OF REED-MULLER CODE RM $(1, m)$ AND CORRESPONDING SIR REQUIREMENTS FOR TARGET BER= 10^{-3}

m	Code Rate	SIR (dB)
2	0.75	6
3	0.5	5.15
4	0.3125	4.6
5	0.1875	4.1
6	0.1094	3.75
7	0.0625	3.45
8	0.0352	3.2
9	0.0195	3.1
10	0.0107	2.8

their transmission rates and consequently the required SIR targets by varying the amount of channel coding for a data packet.

For our simulations we have assumed that all users have packets to transmit at all times (worst case scenario). Multiple users are allowed to transmit at the same time over a shared channel. We assume that users in the network are identical, which means they have an identical action set and identical utility functions associated with the possible actions.

The BER requirement selected for simulations is 10^{-3} , and we assume the use of a Reed-Muller channel code RM $(1, m)$. In table I we show the coding rate combinations and the corresponding SIR target requirements used for our simulations [13].

III. A GAME THEORETIC FRAMEWORK

Game theory represents a set of mathematical tools developed for the purpose of analyzing players interactions in decision processes [8]. It can be used to predict the outcome of these interactions and to identify optimal strategies for the players. The main components of a simple game (strategic or normal form) are the players (assumed to be intelligent and rational), their set of actions or decisions, and a set of preference relationship associated with every action tuple (usually measured by means of a utility function).

In particular, we can model our channel allocation problem as the outcome of a game, in which the players are the cognitive radios, their actions (strategies), are the choice of a transmitting channel and their preferences are associated with the quality of the channels. The quality of channels is determined by the cognitive radios by measurements on different radio frequencies.

We model our channel allocation problem as a normal form game, which can be mathematically defined as $\Gamma = \{N, \{S_i\}_{i \in N}, \{U_i\}_{i \in N}\}$, where N is the finite set of players (decision makers who select a particular channel to transmit), and S_i is the set of strategies associated with player i (channels which could be selected by i).

We define $\mathbb{S} = \times S_i, i \in N$ as the strategy space, and $U_i : \mathbb{S} \rightarrow \mathbb{R}$ as the set of utility functions that the players associate with their strategies. For every player i in game Γ , the utility function U_i is a function of s_i , the strategy selected

by player i , and of the current strategy profile of its opponents: s_{-i} . The utility of user i in our channel allocation game can be considered as the reward received by user i from the network depending on the channel it selects, s_i , and on the other users' choices, s_{-i} . We will discuss shortly how the choice of the utility function affects the outcome of the game.

In analyzing the outcome of the game, as the players make decisions independently and are influenced by the other players' decisions, we are interested to determine if there exist a convergence point for the adaptive channel selection algorithm, from which no player would deviate anymore, i.e. a Nash equilibrium (NE).

Definition: A strategy profile for the players, $S = [s_1, s_2, \dots, s_N]$, is a Nash equilibrium (NE) if and only if

$$U_i(S) \geq U_i(s'_i, s_{-i}), \quad \forall i \in N, s'_i \in S_i. \quad (3)$$

If the equilibrium strategy profile in (3) is deterministic, a pure strategy Nash equilibrium exists. For finite games, even if a pure strategy Nash equilibrium does not exist, a mixed strategy Nash equilibrium can be found (equilibrium is characterized by a set of probabilities assigned to the pure strategies).

As it becomes apparent from the above discussion, the performance of the adaptation algorithm depends significantly on the choice of the utility function which characterizes the preference of a user for a particular channel. The choice of a utility function is not unique. It must be selected to have physical meaning for the particular application, and also to have appealing mathematical properties that will guarantee equilibrium convergence for the adaptation algorithm. We have studied and proposed two different utility functions, that capture the channel quality, as well as the level of cooperation and fairness in sharing the network resources.

A. Utility Functions

The first utility function (U1) we propose accounts for the case of a "selfish" user, which values a channel based on the level of interference perceived on that particular channel:

$$U1_i(s_i, s_{-i}) = - \sum_{j \neq i, j=1}^N p_j G_{ij} f(s_j, s_i). \quad (4)$$

$$\forall i = 1, 2, \dots, N$$

For the above definition, we denoted $P=[p_1, p_2, \dots, p_N]$ as the transmission powers for the N radios, $S=[s_1, s_2, \dots, s_N]$ as the strategy profile and $f(s_i, s_j)$ as an interference function:

$$f(s_i, s_j) = \begin{cases} 1 & \text{if } s_j = s_i, \text{ transmitter } j \text{ and } i \text{ choose} \\ & \text{the same strategy (same channel)} \\ 0 & \text{otherwise} \end{cases}$$

This choice of the utility function requires a minimal amount of information for the adaptation algorithm, namely the interference measurement of a particular user on different channels.

The second utility function we propose accounts for the interference seen by a user on a particular channel, as well

as for the interference this particular choice will create to neighboring nodes. Mathematically we can define U2 as:

$$U2_i(s_i, s_{-i}) = - \sum_{j \neq i, j=1}^N p_j G_{ij} f(s_j, s_i) - \sum_{j \neq i, j=1}^N p_i G_{ji} f(s_i, s_j) \quad (5)$$

$$\forall i = 1, 2, \dots, N$$

The complexity of the algorithm implementation will increase for this particular case, as the algorithm will require probing packets on a common access channel for measuring and estimating the interference a user will create to neighboring radios.

The above defined utility functions characterize a user's level of cooperation, and support a selfish and a cooperative spectrum sharing etiquette, respectively.

B. A Potential Game Formulation

In the previous section we have discussed the choice of the utility functions based on the physical meaning. However, in order to have good convergence properties for the adaptation algorithm we have to ensure that these functions possess certain mathematical properties. There are some classes of games that have been shown to converge to a Nash equilibrium when a best response adaptive strategy is employed. In what follows, we show that for the $U2$ utility function, we can formulate an exact potential game, which converges to a pure strategy Nash equilibrium solution.

Characteristic for a potential game is the existence of a potential function that exactly reflects any unilateral change in the utility function of any player. The potential function models the information associated with the improvement paths of a game instead of the exact utility of the game [17].

An exact potential function is defined as a function

$$P : S \rightarrow \mathbb{R}, \text{ if for all } i, \text{ and } s_i, s'_i \in S_i,$$

with the property that

$$U_i(s_i, s_{-i}) - U_i(s'_i, s_{-i}) = P(s_i, s_{-i}) - P(s'_i, s_{-i}). \quad (6)$$

If a potential function can be defined for a game, the game is an exact potential game. In an exact potential game, for a change in actions of a single player, the change in the potential function is equal to the value of the improvement deviation. Any potential game in which players take actions sequentially converges to a pure strategy Nash equilibrium that maximizes the potential function [17].

For our previously formulated channel allocation game with utility function $U2$, we define an exact potential function to be

$$Pot(S) = Pot(s_i, s_{-i}) = \sum_{i=1}^N \left(-\frac{1}{2} \sum_{j \neq i, j=1}^N p_j G_{ij} f(s_j, s_i) - \frac{1}{2} \sum_{j \neq i, j=1}^N p_i G_{ji} f(s_i, s_j) \right) \quad (7)$$

$$\forall i = 1, 2, \dots, N$$

The function in (7) essentially reflects the network utility. It can thus be seen that the potential game property (6) ensures that an increase in individual users' utilities contributes to the increase of the overall network utility. We note that this property holds only if users take actions sequentially, following a best response strategy.

Hence, to ensure convergence for the spectrum allocation game, either a centralized or a distributed scheduler should be deployed. In an ad hoc network, the latter solution is preferable. To this end, we propose a random access for decision making in which each user is successful with probability $p_a = 1/N$. More specifically, at the beginning of each time slot, each user flips a coin with probability p_a , and, if successful, makes a new decision based on the current values for the utility functions for each channel; otherwise, the user takes no new action. We note that the number of users that attempt to share each channel can be determined from channel listening as we will detail shortly. The proposed random access ensures that on average exactly one user makes decisions at a time, but of course has a nonzero probability that two or more users take actions simultaneously. We have determined experimentally that the convergence of the game is robust to this phenomenon: when two or more users simultaneously choose channels, the potential function may temporarily decrease (decreasing the overall network performance) but then the upward monotonic trend is re-established.

The proposed potential game formulation requires that users should be able to evaluate the candidate channels' utility function U_2 . To provide all the information necessary to determine U_2 , we propose a signaling protocol based on a three way handshake protocol. The signaling protocol is somewhat similar to the RTS-CTS packet exchange for the IEEE 802.11 protocol, but intended as a call admission reservation protocol, rather than a packet access reservation protocol. When a user needs to make a decision on selecting the best transmission frequency (a new call is initiated or terminated, and the user is successful in the Bernoulli trial), such a handshaking is initiated. In contrast to the RTS-CTS reservation mechanism, the signaling packets, START, START_CH and ACK_START_CH (END, ACK_END) in our protocol are not used for deferring transmission for the colliding users, but rather to measure the interference components of the utility functions for different frequencies and to assist in computing the utility function. The signaling packets have a double role: to announce the action of the current user to select a particular channel for transmission, and to serve as probing packets for interference measurements on the selected channel. The signaling packets are transmitted with a fixed transmission power on a common control channel. To simplify the analysis, we assume that no collisions occur on the common control channel. As we mentioned before, the convergence of the adaptation algorithm was experimentally shown to be robust in collision situations. For better frequency planning, it is desirable to use a higher transmission power for the signaling packets than for the transmitted packets. This will permit users to learn the potential interferers over a larger area. For our simulations, we have selected the ratio of transmitted

powers between signaling and data packets to be equal to 2.

We note that the U_2 utility function has two parts: a) a measure of the interference created by others on the desired user, I_d and b) a measure of the interference created by the user on its neighbors' transmissions, I_o . The first part of U_2 can be estimated at the receiving node, whereas the second part can only be estimated at the transmitter node. Therefore, the protocol requires that both transmitter and receiver listen to the control channel and each maintain an information table on all frequencies, similar to the NAV table in 802.11. In what follows, we outline the steps of the protocol.

Protocol steps:

- 1) Bernoulli trial with p_a
if 0, listen to the common control channel; *break*.
if 1, go to 2)
- 2) Transmitter sends START packet: includes current estimates for the interference created to neighboring users on all possible frequencies, $I_o(f)$ (this information is computed based on information saved in the Channel Status Table);
- 3) Receiver computes current interference estimate for the user $I_d(f)$, determines $U_2(f) = -I_d(f) - I_o(f)$ for all channels, and decides on the channel with the highest U_2 (in case of equality, the selection is randomized, with equal probability of selecting the channels);
- 4) Receiver includes the newly selected channel information on a signaling packet *START_CH* which is transmitted on the common channel;
- 5) Transmitter sends *ACK_START_CH* which acknowledges the decision of transmitting on the newly selected frequency, and starts transmitting on the newly selected channel;
- 6) All the other users (transmitters and receivers) that heard the *START_CH* and *ACK_START_CH* packets update their Channel Status Tables (CST) accordingly.

We note that when a call ends, only a two-way handshake is required (END, ACK_END) to announce the release of the channel for that particular user. Upon hearing these end-of-call signaling packets, all transmitters and receivers update their CSTs accordingly.

We can see that a different copy of the CST should be kept at both the transmitter and the receivers (CST_t and CST_r, respectively). The entries of each table will contain the neighboring users that have requested a channel, the channel frequency, and the estimated link gain to the transmitter/receiver of that particular user (for CST_r and CST_t, respectively).

The proposed potential game framework has the advantage that an equilibrium is reached very fast if a best response dynamic is followed, but requires substantial information on the interference created to other users and additional coordination for sequential updates. We note, however, that the sequential updates procedure also resolves the potential conflicts which

may occur upon accessing the common control channel.

The potential game formulation is suitable for designing a cooperative spectrum sharing etiquette, but cannot be used to analyze scenarios involving selfish users, or scenarios involving heterogeneous users (with various utility functions corresponding to different QoS requirements). In the following section, we present a more general design approach, based on no-regret learning techniques, which alleviates the above mentioned problems.

C. Φ -No-Regret Learning for Dynamic Channel Allocation

While we showed in the previous section that the game with the U2 utility function fits the framework of an exact potential game, the U1 function lacks the necessary symmetry properties that will ensure the existence of a potential function. In order to analyze the behavior of the selfish users game, we resort to the implementation of adaptation protocols using regret minimization learning algorithms.

Learning algorithms determine probabilistic strategies for players by considering the history of play. A learning algorithm is characterized by two phases: exploring and exploiting [9]. In the exploring phase, the players try to find the best actions by exploring the entire space of actions. This is achieved by selecting all actions with a non-zero probability. The exploiting phase role is to increase the selection probability of successful strategies.

These types of learning algorithms have traditionally been characterized by regret measures such as external and internal regret, and were not related to equilibrium concepts. External regret is defined as the difference between the payoffs achieved by strategies prescribed by the given algorithm and the payoffs obtained by playing any other fixed sequence of decisions in the worst case. Internal regret is defined as the difference between the payoffs achieved by the strategies prescribed by the given algorithm, and the payoffs that could be achieved by a re-mapped sequence of these strategies. If the payoff difference approaches zero, the algorithm is said to exhibit no-regret.

More recently, studies have been performed to relate the performance of the regret minimization algorithms to game theoretic equilibria [10]. More specifically, in [10], a more general class of no-regret learning algorithms called Φ -no-regret learning algorithms were shown to be related to a class of equilibria named Φ -equilibria. For this class of learning algorithms, Φ determines the set of strategies against the current play should be compared. A learning algorithm is said to satisfy Φ -no-regret, if no regret is experienced by playing as the learning algorithm prescribes, rather than playing according to any transformation of the algorithm's play, characterized by the elements of Φ .

No-external-regret and no-internal-regret learning algorithms are special cases of Φ -no-regret learning algorithm. It is shown in [10] that the empirical distribution of play of Φ -no-regret algorithms converges to a set of Φ -equilibria. It is also shown that no-regret learning algorithms have the potential to learn mixed strategy (probabilistic) equilibria, and

that the tightest game theoretic solution concept to which the Φ -no-regret learning algorithms converge is the correlated equilibrium. We note that a Nash equilibrium is not a necessary outcome of any Φ -no regret learning algorithm [10].

We propose an alternate solution for our spectrum sharing problem, based on the no-external-regret learning algorithm with exponential updates, proposed in [4].

Let $U_i^t(s_i)$ denote the cumulative utility obtained by user i through time t by choosing strategy s_i : $U_i^t(s_i) = \sum_{s=1}^t U_i(s_i, S_{-i}^{s_t})$, where the utility $U_i(s_i, S_{-i}^{s_t})$ is a normalized utility in the range 0 to 1. For $\beta > 0$, the weight (probability) assigned to strategy s_i at time $t + 1$, is given by:

$$w_i^{t+1}(s_i) = \frac{(1 + \beta)^{U_i^t(s_i)}}{\sum_{s'_i \in S_i} (1 + \beta)^{U_i^t(s'_i)}}. \quad (8)$$

A formal proof for the convergence of this learning algorithm is very hard to provide. In [11], based on simulation results, it is shown that the above learning algorithm converges to a Nash equilibrium in games for which a pure strategy Nash equilibrium exists. In this work, we also show by simulations that the proposed channel allocation no-regret algorithm converges to a pure strategy Nash equilibrium for cooperative users (utility U2) and to a mixed strategy equilibrium for selfish users (utility U1).

By following our proposed learning adaptation process, users learn how to choose the frequency channels which maximize their rewards through repeated playing of the game.

For the case of selfish users, the amount of information required by this spectrum sharing algorithm is minimal: users need to measure the interference temperature at their intended receivers (function U1) and to update their weights for channel selection accordingly, to favor the channel with minimum interference temperature (equal transmitted powers are assumed). We note that the no-regret algorithm in (8) requires that the weights are updated for all possible strategies, including the ones that were not played at the time. The reward obtained if other actions had been played can be easily estimated by measuring the interference temperature of all channels.

For the case of cooperative users, the information needed to compute U2 is similar to the case of potential game formulation. We note that, while the learning algorithm does not require sequential updates to converge to an equilibrium, the amount of information exchange on the common control channel requires coordination to avoid collisions. One possible approach to reducing the amount of signaling would be to maintain the access scheme proposed in the previous section, which would ensure that on average only one user at a time will signal changes in channel allocation.

IV. SIMULATION RESULTS

In this section, we present some numerical results to illustrate the performance of the proposed channel allocation algorithms for both cooperative and selfish users' scenarios. For simulation purposes, we consider a fixed wireless ad hoc network (as described in the system model section) with

$N = 30$ and $D = 200$ (30 transmitters and their receivers are randomly distributed over a $200m \times 200m$ square area). The adaptation algorithms are illustrated for a network of 30 transmitting radios, sharing $K = 4$ available channels. A random channel assignment is selected as the initial assignment, and for a fair comparison, all simulations start from the same initial channel allocation.

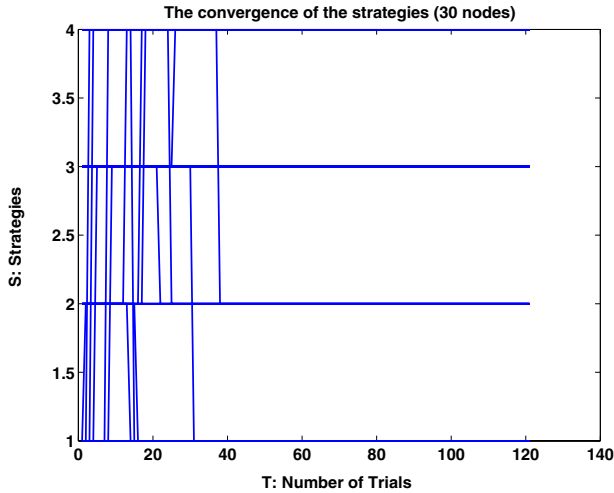

Fig. 2. Potential game: convergence of users' strategies

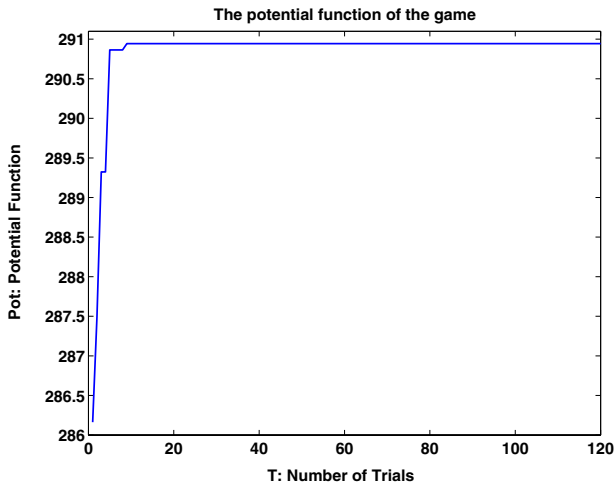

Fig. 3. Evolution of potential function

We first illustrate the convergence properties of the proposed spectrum sharing algorithms. We can see that for cooperative games, both the potential game formulation, as well as the learning solution converge to a pure strategy Nash equilibrium (Figures 2, 4, 10 and 11). In Figure 3, we illustrate the changes in the potential function as the potential game evolves, and it can be seen that indeed by distributively improving their utility, the users positively affect the overall utility of the network, which is approximated by the potential function.

By contrast, the selfish users' learning strategy converges to a mixed strategy equilibrium, as it can be seen in Figures 13

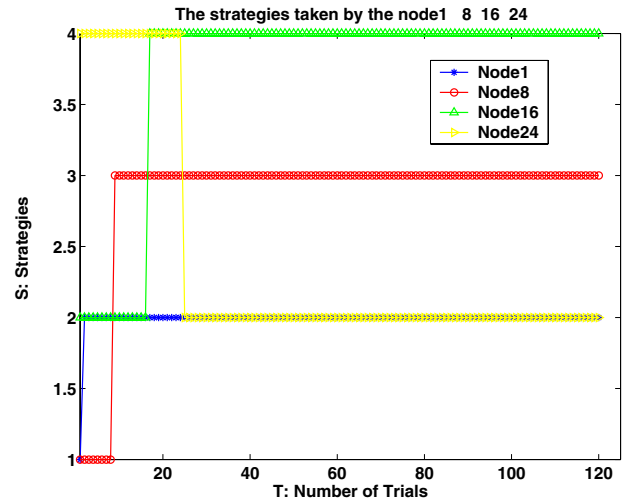

Fig. 4. Potential game: strategy evolution for selected arbitrary users

and 14.

We consider the achieved SIRs and throughputs As performance measures for the proposed algorithms(adaptive coding is used to ensure a certain BER target, as previously explained in Section II). We consider the average performance per user as well as the variability in the achieved performance (fairness), measured in terms of variance and CDF.

We first give results for the potential game based algorithm.

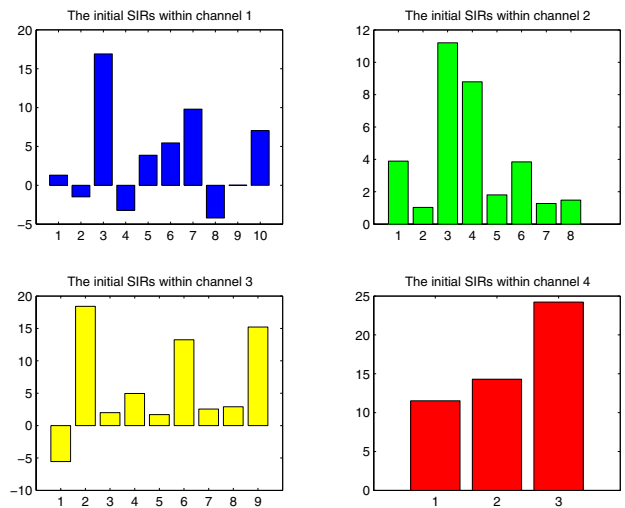

Fig. 5. SIRs for initial channel assignment channels

The choice of the utility function for this game enforces a certain degree of fairness in distributing network resources, as it can be seen in figures 5, 6, 7 and 8. Figures 5 and 6 illustrate the SIR achieved by the users on each of the 4 different channels for initial and final assignments, respectively. We can notice the SIR improvement for the users that initially had a low performance, although it comes at the expense of a slight penalty in performance for users with an initially high SIR. It can be seen in Figure 7 that at the Nash equilibrium point, the

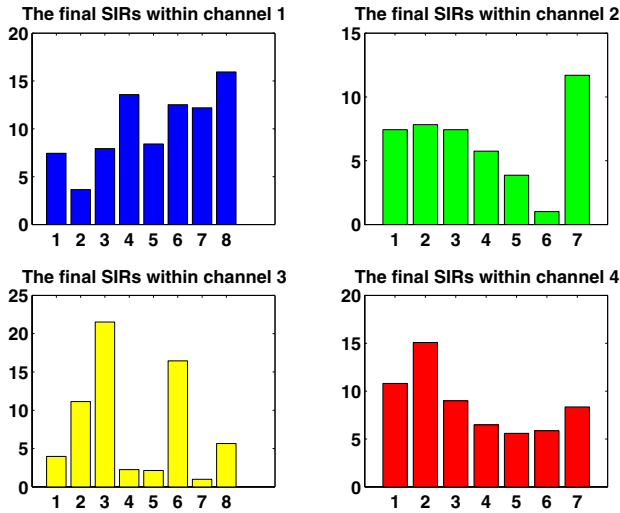

Fig. 6. Potential Game: SIRs at final channel assignment

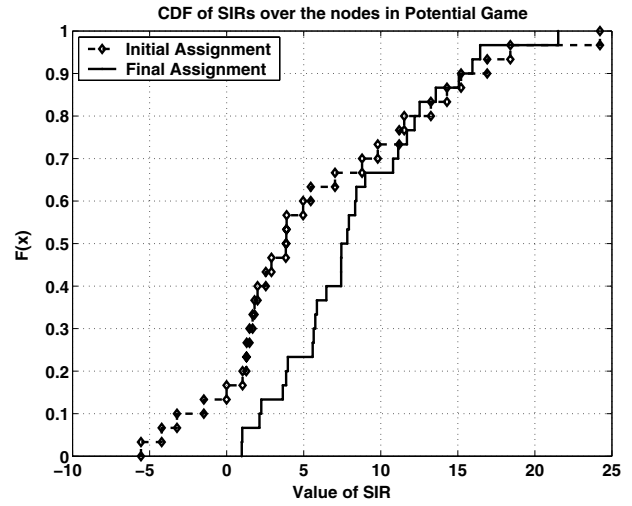

Fig. 8. CDF for the achieved SIRs. Initial Channel Assignment vs. Final Channel Assignment

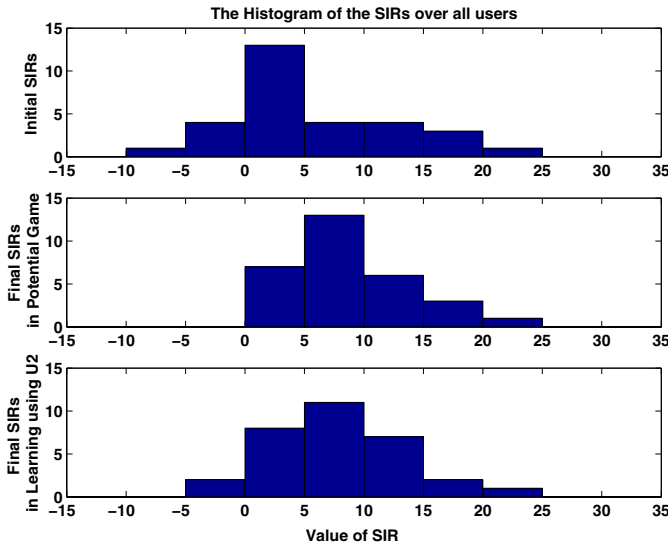

Fig. 7. SIRs histogram. Initial Channel Assignment vs. Final Channel Assignment

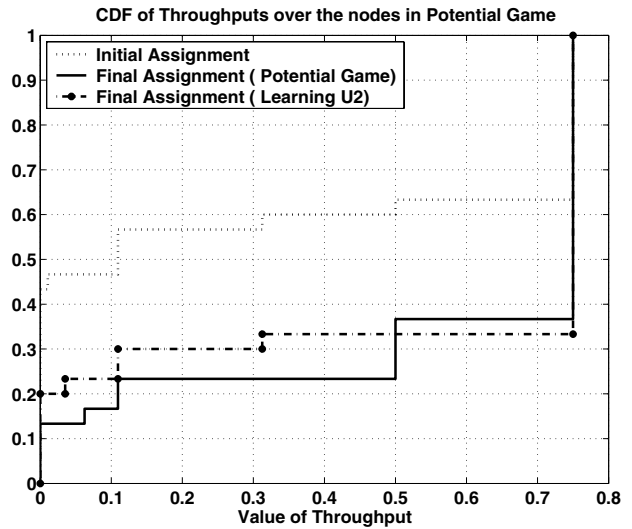

Fig. 9. CDF for the achieved throughputs. Initial Channel Assignment vs. Final Channel Assignment

number of users having an SIR below 0 dB has been reduced. Furthermore, Figure 8 shows that the percentage of users who have an SIR below 5 dB decreases from 60% to about 24%, at the expense of a slight SIR decrease for users with an SIR greater than 12.5 dB.

The advantage of the potential game is illustrated in Figure 9, in terms of the normalized achievable throughput at each receiver. For the initial channel assignment, 62% of the users have a throughput less than 0.75. At the equilibrium, this fraction is reduced to 38%. Aggregate normalized throughput improvements for the potential game formulation are illustrated in Table II.

Our simulation results show very similar performances for the learning algorithm in cooperative scenarios with the potential game formulation. Figures 7 and 12 show the initial and final assignment for this algorithm, as well as the achieved

SIRs after convergence for all users in the network. In terms of fairness, the learning algorithm performs slightly worse than the potential game formulation (Figure 9). However, even though the equilibrium point for learning is different than that of the potential game, the two algorithms achieve very close throughput performance (Table II).

As we previously mentioned, the learning algorithm for selfish users does not lead to a pure strategy Nash equilibrium channel allocation. In Figure 13 we illustrate the convergence properties for an arbitrarily chosen user, which converge to a mixed strategy allocation: selects channel 1 with probability 0.575 or channel 3 with probability 0.425. The evolutions of the weights for all the users in the network are shown in Figure 14.

We compare the performance of the proposed algorithms for both cooperative and non-cooperative scenarios. The per-

Final (Potential Game)	16.5
Final (Learning U2)	15.3

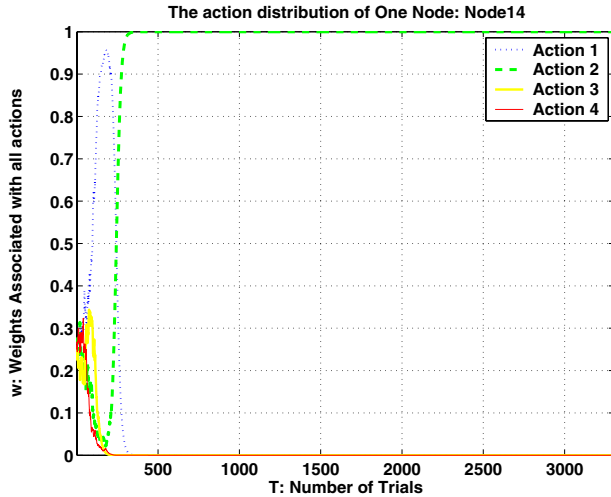

Fig. 10. No-regret learning for cooperative users: weights distribution evolution for an arbitrary user

formance measures considered are the average SIR, average throughput per user and total average throughput for the network. At the beginning of each time slot, every user will either choose the same equilibrium channel for transmission (in cooperative games with pure strategy Nash equilibrium solutions), or will choose a channel to transmit with some probability given by the mixed strategy equilibrium (i.e. learning using U1). In the random channel allocation scheme, every user chooses a channel with equal probability from a pool of four channels.

Figure 15 shows the CDF of the Time Average SIR in different games. All learning games and the potential game outperform the random channel allocation scheme. The potential game has the best throughput performance, followed closely by the cooperative learning scheme. It can be seen in Figure 16 that half of the users have an average throughput below 0.3 in the random allocation scheme. The percentage of users whose average throughput is below 0.3 is 23% in potential game, 27% for learning using U2 and 34% for learning using U1, while the fraction is 51% for the random selection.

In Figure 17 we summarize performance comparisons among the proposed schemes: total average throughput, average throughput per user and variance of the throughput per user. The variance performance measure quantifies the fairness, with the fairest scheme achieving the lowest variance. Among all the proposed schemes, the potential channel

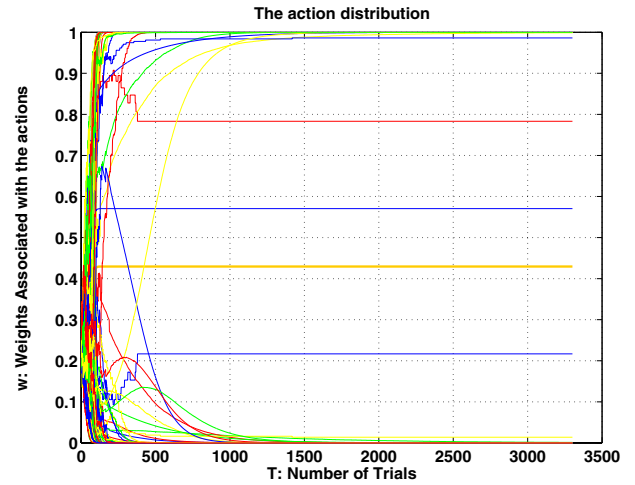

Fig. 11. No-regret learning for cooperative users: weights distribution evolution for all users

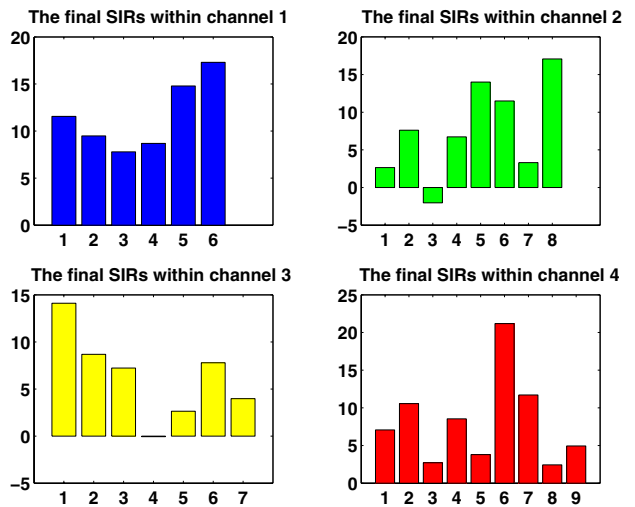

Fig. 12. No-regret learning for cooperative users: SIR of users in different channels at Nash equilibrium

allocation game has the best performance. It is interesting to note that in terms of average obtained throughput per user, the three schemes perform similarly but differ in the performance variability across users. It seems that even when cooperation is enforced by appropriately defining the utility, the potential game formulation provides a fairness advantage over the no-regret learning scheme.

V. CONCLUSION

In this work, we have investigated the design of channel sharing etiquette for cognitive radio networks for both cooperative and non-cooperative scenarios. Two different formulations for the channel allocation game were proposed: potential game formulation, and no-regret learning. We showed that all the proposed spectrum sharing policies converge to a channel allocation equilibrium, although a pure strategy allocation can be achieved only for cooperative scenarios. Our simulation

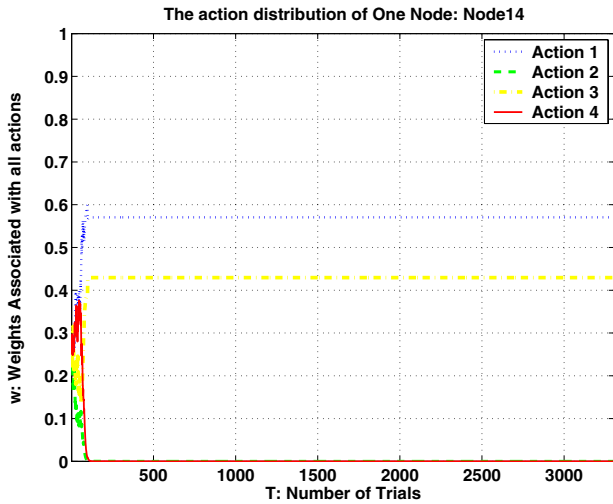

Fig. 13. No-regret learning for selfish users: weights evolution for an arbitrary user

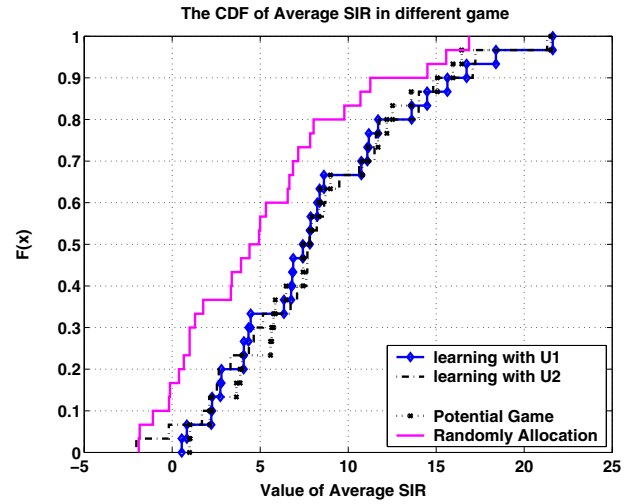

Fig. 15. The CDF of Time Average SIRs

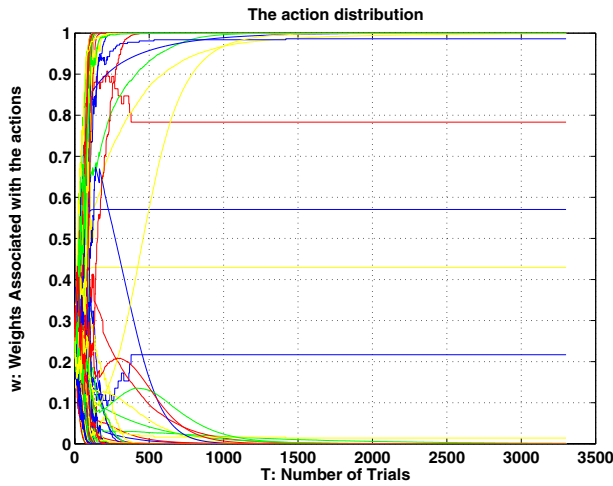

Fig. 14. No-regret learning for selfish users: Evolution of weights for all users

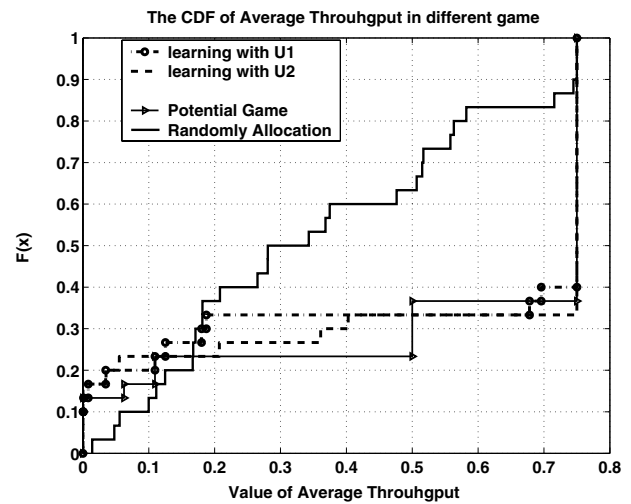

Fig. 16. The CDF of Average Throughput

results have showed that the average performance in terms of SIR or achievable throughput is very similar for both learning and potential game formulation, even for the case of selfish users. However, in terms of fairness, we showed that both cooperation and allocation strategy play important roles. While the proposed potential game formulation yields the best performance, its applicability is limited to cooperative environments and significant knowledge about neighboring users is required for the implementation. By contrast, the proposed no-regret learning algorithm is suitable for non-cooperative scenarios and requires only a minimal amount of information exchange.

This work represents a first step in understanding the spectrum sharing problem for cognitive radio networks. In future work, we will extend the proposed solutions to address more practical scenarios, such as the case of users with unequal powers, power controlled networks, as well as the

case of heterogeneous users, characterized by different utility functions.
